1 Transition path theory formalism

1.1 The transition path ensemble

We begin a quantitative description of transition paths by formalizing the ensemble notion. The theoretical development parallels [12], but expands on it in several ways that we will clarify. Consider the stratosphere, or any other stochastic ergodic dynamical system, evolving through a very long time interval $(-T, T)$, during which it crosses from A to B and back a number M_T of times. As $T \to \infty$, ergodicity guarantees that $M_T \to \infty$ as well. The mth transition path begins at time τ_m^- (so $\mathbf{X}(\tau_m^-) \in A$[1]) and ends at time τ_m^+ (so $\mathbf{X}(\tau_m^+) \in B$). Each τ_m^- marks the beginning of an orange segment in Fig. 2, and τ_m^+ marks the end of it.

At the first level, we consider the set of *transition snapshots*, which are the instantaneous model states $\mathbf{X}(t)$ realized in the course of a transition without regard to their ordering in time or their grouping into separate transition events:

$$\text{Transition snapshots} = \bigcup_{m=1}^{\infty} \bigcup_{t=\tau_m^-}^{\tau_m^+} \mathbf{X}(t). \tag{1}$$

This ensemble is described completely by the densities such as π_{AB} and π_{BA} in the right-hand column of Fig. 2, which lump together all reactive snapshots into a single distribution, regardless of which transition event they came from. In other words, every orange point in Fig. 1 (c) and (d) contributes one sample to the ensemble. The reactive densities describe how the stratosphere looks at a single moment in transition, but not how it evolves through the transition.

At the second level, we distinguish each transition path as a unique, coherent object, containing a sequence of snapshots ordered in time. We formally define the $(A \to B)$ transition path ensemble as

$$\text{Transition paths} = \tag{2}$$

$$\left\{ \{(t, \mathbf{X}(t)), \tau_m^- \leq t < \tau_m^+ \}, m = 1, 2, \ldots \right\} \tag{3}$$

---

[1]Technically, we assume $\mathbf{X}(t)$ is right-continuous with left limits, meaning $\mathbf{X}(\tau_m^-) \notin A$ but $\lim_{t \uparrow \tau_m^-} \mathbf{X}(t) \in A$. This detail is not important for us here.

The inner set is the collection of snapshots along the mth transition path, and the outer set is the collection of paths, which becomes infinite as $T \to \infty$. There is no fixed duration of transition paths; each one has a different duration $\tau_m^+ - \tau_m^-$. For this reason, the space of paths has infinite dimension. Therefore, there is no probability density to describe the path ensemble. However, *functionals* of transition paths do have well-defined distributions. Using the abbreviation $\mathbf{X}^{(m)} := \{(t, \mathbf{X}(t)) : \tau_m^- \leq t < \tau_m^+\}$ for the mth transition path, we can define arbitrary functionals $\mathscr{G}$ such as

$$\mathscr{G}[\mathbf{X}^{(m)}] = \tau_m^+ - \tau_m^-, \tag{4}$$

$$\mathscr{G}[\mathbf{X}^{(m)}] = \int_{\tau_m^-}^{\tau_m^+} \overline{v'T'}(30\,\text{km})\, dt, \tag{5}$$

$$\mathscr{G}[\mathbf{X}^{(m)}] = \max \left\{ \left| \frac{U(30\,\text{km})(t_2) - U(30\,\text{km})(t_1)}{t_2 - t_1} \right| : \tau_m^- \leq t_1 < t_2 \leq \tau_m^+ \right\}, \tag{6}$$

which quantify the elapsed time, the total heat flux at 30 km, and the fastest drop in wind speed at 30 km recorded over the whole transition path. (A time derivative is not technically well-defined for a white noise-driven process.) The quantities of interest $\mathscr{G}$ will, of course, depend on the application. For any fixed scalar-valued or vector-valued $\mathscr{G}$, the collection of random variables $\{\mathscr{G}[\mathbf{X}^{(1)}], \mathscr{G}[\mathbf{X}^{(2)}], \ldots\}$ has a well-defined steady-state distribution that we wish to characterize. In principle, we could do this by "direct numerical simulation" (DNS): integrate the system for a long time, collect many $A \to B$ transition paths $\mathbf{X}^{(m)}$, calculate $\mathscr{G}[\mathbf{X}^{(m)}]$ for each one, and estimate summary statistics. Although DNS is simple and general, it is expensive for high-dimensional models, particularly for rare event simulation. The DGA method, explained below in section 2, circumvents DNS by using only short trajectories, short not only compared to the return time $\tau_{m+1}^- - \tau_m^+$, but even compared to the $(A \to B)$ transit time $\tau_m^+ - \tau_m^-$. We focus on functionals of the form (26), repeated here for reference:

$$\mathscr{G}[\mathbf{X}^{(m)}] = \int_{\tau_m^-}^{\tau_m^+} \Gamma(\mathbf{X}(t))\, dt \tag{7}$$

where Γ is a user-defined quantity of interest. For example $\Gamma(\mathbf{x}) = 1$ yields the transit time (4) and $\Gamma = \overline{v'T'}(30\,\text{km})$ yields the total heat flux at 30 km, (5). For certain extreme weather events, Γ might be chosen to measure accumulated damage of some kind, say, the total rainfall deposited over an area (in the case of hurricanes) or total time with surface temperatures above a certain threshold (in the case of heat waves). In a downward-coupled SSW model, one could define Γ to reflect the human impact of extreme cold spells, but in the simple Holton-Mass model we value Γ only for dynamical insight into SSW variability. We will refer to $\int \Gamma(\mathbf{X}(t))\, dt$ as a *transition path integral*. A limitation of DGA is that it cannot directly handle more complex nonlinear functionals of the form (6). We will return to address this issue later on.

The essential insight of TPT is to express these quantities of interest in terms of a set of *forecast functions*. We follow the formulation of TPT in [12], but expand upon it substantially to include a broader class of transition path statistics, as required by this application. Subsequently, we will describe the computational method that uses only short trajectories.

1.1.1 Forecast functions

A forecast is an estimate of the future conditioned on the present, which in probability language takes the form

$$F^+(\mathbf{x}) = \mathbb{E}_{\mathbf{x}}[Q(\{(t, \mathbf{X}(t)) : t \geq 0\})]. \tag{8}$$

2

Here, $\mathbb{E}_{\mathbf{x}}$ indicates a conditional expectation given a fixed initial condition $\mathbf{X}(0) = \mathbf{x}$ (we can set $t_0 = 0$ when assuming autonomous dynamics). Q is a generic functional of the future evolution of the state $\mathbf{X}(t)$. It is explicitly a random variable under the stochastic forcing we impose here, but even in a deterministic model, uncertainty from initial conditions and model error lead to effective randomness. For example, Q could return 1 if $\mathbf{X}(t)$ next hits B before A, and 0 if $\mathbf{X}(t)$ next hits A before B. This makes F^+ simply the forward committor, as introduced in section 3:

$$F^+(\mathbf{x}) = \mathbb{E}_{\mathbf{x}}\left[\mathbb{1}_B(\mathbf{X}(\tau^+))\right] \tag{9}$$

$$= \mathbb{P}_{\mathbf{x}}\{\mathbf{X}(\tau^+) \in B\} =: q^+(\mathbf{x}) \tag{10}$$

We might also wish to forecast the time it takes to get there, by defining $Q = \tau^+ \mathbb{1}_B(\mathbf{X}(\tau^+))$ and making $F^+(\mathbf{x})/q^+(\mathbf{x})$ the (conditional) mean first passage time. Both of these functions were estimated in [3], and are useful in their own right for real-time forecasting and analysis of those forecasts.

As explained in section 3(c), the forward committor only looks to the future, and the backward committor is needed to single out the $A \rightarrow B$ phase.

$$q^-(\mathbf{x}) = \mathbb{E}_{\mathbf{x}}[\mathbb{1}_A(\mathbf{X}(\tau^-))] = \mathbb{P}_{\mathbf{x}}\{\mathbf{X}(\tau^-) \in A\} \tag{11}$$

This is a backward-in-time forecast, or *aftcast*.

Forward and backward committors are central components in the existing transition path theory laid out in [2, 12, 7, 6, 13], and elsewhere. Here, we generalize committors to forecast not only where the trajectory ends up, but what happens along the way. We consider forecast/aftcast functions of the form

$$F_\Gamma^+(\mathbf{x}; \lambda) = \mathbb{E}_{\mathbf{x}}\left[\mathbb{1}_B(\mathbf{X}(\tau^+)) \exp\left(\lambda \int_0^{\tau^+} \Gamma(\mathbf{X}(r)) \, dr\right)\right] \tag{12}$$

$$F_\Gamma^-(\mathbf{x}; \lambda) = \mathbb{E}_{\mathbf{x}}\left[\mathbb{1}_A(\mathbf{X}(\tau^-)) \exp\left(\lambda \int_{\tau^-}^0 \Gamma(\mathbf{X}(r)) \, dr\right)\right] \tag{13}$$

where λ is a real free parameter. With $\lambda = 0$ (and any Γ), F_Γ^+ and F_Γ^- in (12) and (13) reduce to the forward and backward committors. We can use the fact that the past and future are independent *conditional on the present*, and multiply them together to get an expectation over transition paths crossing through $\mathbf{x}$:

$$F_\Gamma^-(\mathbf{x}, \lambda) F_\Gamma^+(\mathbf{x}, \lambda) = \tag{14}$$
$$\mathbb{E}_{\mathbf{x}}\left[\mathbb{1}_A(\mathbf{X}(\tau^-))\mathbb{1}_B(\mathbf{X}(\tau^+)) \exp\left(\lambda \int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r)) \, dr\right)\right]$$

This product is now seen to be a moment-generating function for the transition path integral (7). Differentiating in λ at $\lambda = 0$ provides us with any moment of the path integral distribution:

$$\partial_\lambda^k \left[F^-(\mathbf{x}, \lambda) F_\Gamma^+(\mathbf{x}, \lambda)\right]_{\lambda=0} = \tag{15}$$
$$\mathbb{E}_{\mathbf{x}}\left[\mathbb{1}_A(\mathbf{X}(\tau^-))\mathbb{1}_B(\mathbf{X}(\tau^+))\left(\int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r)) \, dr\right)^k\right]$$

where, again, the expectation is restricted to paths crossing through $\mathbf{x}$. Setting $k = 0$, this is simply $q^+(\mathbf{x})q^-(\mathbf{x})$, the probability of an observed snapshot $\mathbf{x}$ being part of a transition path, which is shown in Fig. 4(c). With $k \geq 1$, it is natural to condition on snapshots being reactive by dividing by

$q^+(\mathbf{x})q^-(\mathbf{x})$.

$$\frac{\partial_\lambda^k [F_\Gamma^+(\mathbf{x};\lambda)F_\Gamma^-(\mathbf{x};\lambda)]_{\lambda=0}}{q^+(\mathbf{x})q^-(\mathbf{x})} \tag{16}$$

$$= \mathbb{E}_\mathbf{x}\left[\left(\int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r))\,dr\right)^k \middle| \mathbf{X}(\tau^-) \in A, \mathbf{X}(\tau^+) \in B\right]$$

$$= \mathbb{E}_\mathbf{x}\left[\left(\int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r))\,dr\right)^k \middle| A \to B\right] \text{ (abbreviation)}$$

As a function of $\mathbf{x}$, these *forecast maps* describe the character of transition paths that take different routes through state space. We have already displayed forecast maps in Fig. 8, $\Gamma = 1$ and $\Gamma = \overline{v'T'}$(30 km).

Everything we say about transition paths stems originally from the functions F_Γ^+ and F_Γ^- for various Γ, as well as the steady-state distribution π. More specifically, we need the ability to compute $\partial_\lambda^k F_\Gamma^\pm(\mathbf{x};0)$ for any $k \geq 0$ and for any user-defined Γ. Thus, we spend the remainder of this section defining the quantities of interest, some of which have already been seen in the results, and then expressing them in terms of F_Γ^+, F_Γ^-, and π. Section 2 will then explain how to compute them using short simulation data.

1.1.2 Reactive snapshot averages

In this subsection, we use committors to define statistics over the transition path ensemble at the level of snapshots, or equivalently, averages with respect to the reactive densities π_{AB} and π_{BA}. The following subsection does the same at the level of paths, and uses the more general $F_\Gamma^\pm$ forecasts rather than just committors. The key to transforming forecasts into ensemble averages (at either level) is the *ergodic assumption*, which says that for any suitable observable $\Gamma(\mathbf{x})$, time averaging is equivalent to spatial averaging with respect to the steady-state distribution π:

$$\lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} \Gamma(\mathbf{X}(t))\,dt = \int_{\mathbb{R}^d} \Gamma(\mathbf{x})\pi(\mathbf{x})\,d\mathbf{x} =: \langle\Gamma\rangle_\pi \tag{17}$$

For example, if S is a small region of $\mathbb{R}^d$ and $\Gamma(\mathbf{x}) = \mathbb{1}_S(\mathbf{x})$, the formula (17) says that the fraction of time $\mathbf{X}(t)$ spends in S is equal to the total mass of π contained in S. While Equation (17) gives us equilibrium averages over the system's entire history, describing reactive snapshots means restricting the time horizon $(-T, T)$ to times when $\mathbf{X}(t)$ is en route from A to B. The ergodic assumption easily allows for this in two steps. First, we find the time fraction that $\mathbf{X}(t)$ is reactive during $(-T, T)$:

$$\text{Fraction of time reactive} = \lim_{T \to \infty} \frac{1}{2T} \sum_{m=1}^{M_T} (\tau_m^+ - \tau_m^-)$$

$$= \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} \mathbb{1}_A(\mathbf{X}(\tau^-(t)))\mathbb{1}_B(\mathbf{X}(\tau^+(t)))\,dt$$

$$= \int_{\mathbb{R}^d} \mathbb{E}_\mathbf{x}\left[\mathbb{1}_A(\mathbf{X}(\tau^-))\mathbb{1}_B(\mathbf{X}(\tau^+))\right]\pi(\mathbf{x})\,d\mathbf{x}$$

$$= \int_{\mathbb{R}^d} q^-(\mathbf{x})q^+(\mathbf{x})\pi(\mathbf{x})\,d\mathbf{x} = \langle q^- q^+\rangle_\pi \tag{18}$$

Inserting Γ into the integral above and normalizing gives us a restricted average:

$$\text{Average of } \Gamma \text{ over reactive snapshots} = \frac{\langle \Gamma q^- q^+ \rangle_\pi}{\langle q^- q^+ \rangle_\pi} \tag{19}$$

$$= \int \Gamma(\mathbf{x}) \frac{q^-(\mathbf{x}) q^+(\mathbf{x}) \pi(\mathbf{x})}{\langle q^- q^+ \rangle_\pi} \, d\mathbf{x} =: \langle \Gamma \rangle_{\pi_{AB}}$$

The fraction in the last integral, $q^- q^+ \pi / \langle q^- q^+ \rangle_\pi$, is a properly normalized probability density that defines the reactive density $\pi_{AB}(\mathbf{x})$, the orange curves in Fig. 2 and the background shading in Fig. 5(c,e). The $(B \to A)$ density π_{BA}, is obtained in the same way, but switching the roles of A and B or by taking complements of probabilities, i.e., $\pi_{BA} = \pi(1 - q^-)(1 - q^+) / \langle (1 - q^-)(1 - q^+) \rangle_\pi$. The phases $A \to A$ and $B \to B$ can be characterized similarly.

1.1.3 Transition path averages and currents

Thinking about transition paths from start to finish as discrete, coherent objects unlocks a richer description of the rare event, which is ultimately related to the reactive currents. In this section we use forecast functions (12) and (13) to compute the transition rate and statistics of the path integrals (7) with a single framework centered around the *generalized symmetric rate*:

$$R_\Gamma(\lambda) := \lim_{T \to \infty} \frac{1}{2T} \sum_{m=1}^{M_T} \exp\left(\lambda \int_{\tau_m^-}^{\tau_m^+} \Gamma(\mathbf{X}(r)) \, dr \right) \tag{20}$$

The notation emphasizes that R_Γ depends on the observable Γ and the real parameter λ. To unpack this formula, first set $\lambda = 0$ and observe that $R_\Gamma(0) = \frac{M_T}{2T}$ is the number of transitions per unit time, or symmetric rate, whose inverse is the average period of the full SSW life cycle. This is not to be confused with the asymmetric forward and backward rates,

$$k_{AB} = \frac{R_\Gamma(0)}{\langle q^- \rangle_\pi}, \qquad\qquad k_{BA} = \frac{R_\Gamma(0)}{\langle 1 - q^- \rangle_\pi} \tag{21}$$

which distinguish the $A \to B$ and $B \to A$ directions by how fast they occur. The factor $\langle q^- \rangle_\pi$ is the time fraction spent *having last been in A* rather than B, and $\langle 1 - q^- \rangle$ is the opposite. For example, if A were very stable and B very unstable, the system would spend most of its time in the basin of attraction of A, making $\langle q^- \rangle_\pi$ large and $k_{AB} \ll k_{BA}$. Asymmetric rates (or "rate constants") are very important for chemistry applications, but the symmetric rate is more useful to us presently.

All of these rates have been studied extensively with TPT and preceding theories. Our novel contribution is to introduce the exponential factor $\exp\left(\lambda \int \Gamma(\mathbf{X}(t)) \, dt \right)$ to additionally study transition path integrals. The theoretical development below therefore reduces to classical TPT by replacing Γ with 0.

Returning to (20), we divide through by $R_\Gamma(0)$:

$$\frac{R_\Gamma(\lambda)}{R_\Gamma(0)} = \lim_{T \to \infty} \frac{1}{M_T} \sum_{m=1}^{M_T} \exp\left(\lambda \int_{\tau_m^-}^{\tau_m^+} \Gamma(\mathbf{X}(r)) \, dr \right)$$

$$= \mathbb{E}_{\text{paths}} \left[\exp\left(\lambda \int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r)) \, dr \right) \right] \tag{22}$$

where the subscript "paths" distinguishes the expectation as over *all* transition paths, not just those crossing through a fixed $\mathbf{x}$ as in (16). The right side of (22) is a moment-generating function for the

transition path integral (7). Differentiating in λ yields the moments of that distribution, including its variance, skew, and kurtosis:

$$\frac{\partial_\lambda^k R_\Gamma(0)}{R_\Gamma(0)} = \mathbb{E}_{\text{paths}}\left[\left(\int_{\tau^-}^{\tau^+} \Gamma(\mathbf{X}(r))\,dr\right)^k\right], \tag{23}$$

Thus, $R_\Gamma(\lambda)$ contains much information about the transition ensemble as measured by path integrals.

We now express R_Γ in terms of the forecast functions F_Γ^+ and F_Γ^-, again using the key assumption of ergodicity. We must convert Equation (20), a sum over transition paths $\sum_{m=1}^{M_T}(\cdot)$, into an integral over time $\int_{-T}^{T}(\cdot)\,dt$ and then (by ergodicity) into an integral over space $\int_{\mathbb{R}^d}(\cdot)\pi(\mathbf{x})\,d\mathbf{x}$. This approach extends the rate derivation in [12] and [10] to generalized rates.

To write the rate as a time integral, we introduce a dividing surface between A and B (such as a committor level surface) and use the fact that a transition path crosses such a surface an odd number of times. A mask is applied to the time integral to select only the time segments when a reactive trajectory segment is crossing this surface (+1 for positive crossings and −1 for negative crossings), resulting in unit weight for each transition path. To be more explicit, let S be a region of state space that contains A and excludes B, so that its boundary ∂S is a dividing surface between A and B. The generalized rate (20) can then be written as the following time integral:

$$R_\Gamma(\lambda) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} \tag{24}$$

$$\exp\left(\lambda \int_{\tau^-(t)}^{\tau^+(t+\Delta t)} \Gamma(\mathbf{X}(r))\,dr\right) \times \tag{25}$$

$$\mathbb{1}_A(\mathbf{X}(\tau^-(t)))\,\mathbb{1}_B(\mathbf{X}(\tau^+(t+\Delta t))) \times \tag{26}$$

$$\left[\mathbb{1}_S(\mathbf{X}(t))\,\mathbb{1}_{S^c}(\mathbf{X}(t+\Delta t)) \right. \tag{27}$$

$$\left. -\mathbb{1}_{S^c}(\mathbf{X}(t))\,\mathbb{1}_S(\mathbf{X}(t+\Delta t))\right]dt \tag{28}$$

The idea is to restrict the interval $(-T, T)$ to the collection of time intervals $(t, t+\Delta t)$ during which the path crosses the surface ∂S. Line (26) applies a mask picking out transition path segments, which are those that come from A and next go to B. Line (27) applies a further mask picking out the narrow time intervals when $\mathbf{X}(t)$ exits the region from S to S^c, while line (28) subtracts the backward crossings from S^c to S. Using ergodicity, we can replace the time integral with a space integral and insert conditional expectations inside. For example, the part of the integrand

$$\exp\left(\lambda \int_{t+\Delta t}^{\tau^+(t+\Delta t)} \Gamma(\mathbf{X}(r))\,dr\right) \times \tag{29}$$

$$\mathbb{1}_B(\mathbf{X}(\tau^+(t+\Delta t)))\,\mathbb{1}_{S^c}(\mathbf{X}(t+\Delta t))$$

becomes, after taking conditional expectations,

$$\mathbb{E}\left[\mathbb{1}_{S^c}(\mathbf{X}(t+\Delta t))F_\Gamma^+(\mathbf{X}(t+\Delta t))\big|\mathbf{X}(t) = \mathbf{x}\right] \tag{30}$$

$$=: \mathcal{T}^{\Delta t}\left[\mathbb{1}_{S^c}F_\Gamma^+\right](\mathbf{x})$$

Where the *transition operator* is defined as $\mathcal{T}^{\Delta t}f(\mathbf{x}) = \mathbb{E}_\mathbf{x}[f(\mathbf{X}(\Delta t))]$. Applying similar logic to all

terms in the integrand, we have the following generalized rate formula:

$$R_\Gamma(\lambda) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x}; \lambda) \times \tag{31}$$

$$\left\{ \mathbb{1}_S \mathcal{T}^{\Delta t} \left[\mathbb{1}_{S^c} F_\Gamma^+ \right] - \mathbb{1}_{S^c} \mathcal{T}^{\Delta t} \left[\mathbb{1}_S F_\Gamma^+ \right] \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x}$$

which holds for any dividing surface S. This is a form estimable from short simulation data, which the next section will explain.

The rate formula (31) is suggestive of a surface integral, counting hopping events across the surface ∂S. In fact, the reactive current $\mathbf{J}_{AB}$ is defined as the vector field whose surface integral is equal to the symmetric rate:

$$R_\Gamma(0) = \int_{\partial S} \mathbf{J}_{AB} \cdot \mathbf{n} \, d\sigma \tag{32}$$

We have visualized $\mathbf{J}_{AB}$ in section 3 using a discretization of the integrand in (31). Note that the integral does *not* depend on the specific dividing surface we choose, which implies that $\mathbf{J}_{AB}$ is divergence-free outside of $A \cup B$, but has a source of field lines at A and a sink at B. Since every dividing surface supports the same total flux, large local current magnitude means a constrained reaction mechanism, as demonstrated by the early transition states in Fig. 6.

We have now completely described the mathematics of TPT, and our extensions to it. Exact knowledge of π, F_Γ^+, F_Γ^-, and their derivatives is enough to generate all of the figures shown so far. The next section explains both how to compute these fundamental ingredients from data and assemble them into generalized rates.

2 Numerical method: dynamical Galerkin approximation (DGA)

2.1 Feynman-Kac formulae

We now sketch the numerical method, following [11, 10], and [3]. Equations (12) and (13) involve an integral in time all the way from $t = 0$ to $t = \tau^+$ or (in backward time) to τ^-, when $\mathbf{X}(t)$ hits either A or B after wandering through state space for an indeterminate period. This would seem to require long trajectories to estimate. Amazingly, it turns out that $F_\Gamma^\pm$ obey partial differential equations called Feynman-Kac formulae [8, 5, 1], which are fully *local* in state space and can be discretized using only short trajectories. The Feynman-Kac formulae read

$$\begin{cases} (\mathcal{L} + \lambda\Gamma(\mathbf{x}))F_\Gamma^+(\mathbf{x}; \lambda) = 0 & \mathbf{x} \in D \\ F_\Gamma^+(\mathbf{x}) = 0 & \mathbf{x} \in A \\ F_\Gamma^+(\mathbf{x}) = 1 & \mathbf{x} \in B \end{cases} \tag{33}$$

$$\text{where } \mathcal{L}\phi(\mathbf{x}) := \lim_{\Delta t \to 0} \frac{\mathbb{E}_\mathbf{x}[\phi(\mathbf{X}(\Delta t))] - \phi(\mathbf{x})}{\Delta t} \tag{34}$$

$$\begin{cases} (\widetilde{\mathcal{L}} + \lambda\Gamma(\mathbf{x}))F_\Gamma^-(\mathbf{x}; \lambda) = 0 & \mathbf{x} \in D \\ F_\Gamma^-(\mathbf{x}) = 1 & \mathbf{x} \in A \\ F_\Gamma^-(\mathbf{x}) = 0 & \mathbf{x} \in B \end{cases} \tag{35}$$

$$\text{where } \widetilde{\mathcal{L}}\phi(\mathbf{x}) := \lim_{\Delta t \to 0} \frac{\mathbb{E}_\mathbf{x}[\phi(\mathbf{X}(-\Delta t))] - \phi(\mathbf{x})}{\Delta t} \tag{36}$$

7

The linear operators $\mathcal{L}$ and $\widetilde{\mathcal{L}}$ are known as the forward and backward infinitesimal generators, pushing observable functions ϕ forward or backward in time analogously to a material derivative in fluid mechanics. The backward-in-time expectations are defined specifically for the *equilibrium* process, leading to $\widetilde{\mathcal{L}}\phi(\mathbf{x}) = \frac{1}{\pi(\mathbf{x})}\mathcal{L}^*[\pi\phi](\mathbf{x})$, where $\mathcal{L}^*$ is the adjoint of $\mathcal{L}$ with respect to the reference (Lebesgue) measure $d\mathbf{x}$. Equivalently, $\widetilde{\mathcal{L}}$ is the adjoint of $\mathcal{L}$ with respect to the steady-state measure $\pi(\mathbf{x})\,d\mathbf{x}$. In addition, we have the stationary Fokker-Planck equation for π itself:

$$\begin{cases} \mathcal{L}^*\pi(\mathbf{x}) = 0 & \mathbf{x} \in \mathbb{R}^d \\ \int_{\mathbb{R}^d}\pi(\mathbf{x})\,d\mathbf{x} = 1 \end{cases} \tag{37}$$

We can further obtain equations for the derivatives of $F_\Gamma^\pm$ with respect to λ, using the Kac moment method [4] as also described in [3]. Differentiating the equation (34) itself in λ and setting $\lambda = 0$ yields a recursive sequence of equations for the higher derivatives of F_Γ^+:

$$\mathcal{L}\big[\partial_\lambda^k F_\Gamma^+\big](\mathbf{x};0) = -k\Gamma\partial_\lambda^{k-1}F_\Gamma^+(\mathbf{x};0), \qquad\qquad k \geq 1, \tag{38}$$

with boundary conditions $\partial_\lambda^k F_\Gamma^+\big|_{A\cup B} = 0$. The same procedure can be applied to the aftcast F_Γ^-. The product rule immediately provides all the moments $\partial_\lambda^k[F_\Gamma^+(\mathbf{x},\lambda)F_\Gamma^-(\mathbf{x},\lambda)]_{\lambda=0}$, as needed for the forecast maps (15). Thus, our entire numerical pipeline boils down to solving equations of the form (33), (35), and (37). (Eq. (38) is a special case of (35), and the corresponding backward-time version is a special case of (33), once the right-hand sides are known.)

2.2 Discretization of Feynman-Kac formulae

We will now describe how to discretize and solve these three equations, which requires three similar but distinct procedures.

First we attack (33). The generator of a diffusion processes can be expressed as a partial differential operator, and so the above equations are PDEs over state space. PDEs cannot be practically discretized in high dimensions, but the essential property of spatial locality allows for data-driven approximation with short trajectories, using the probabilistic definition in (34) and (36). This is how we use our large data set of short trajectories,

$$\{\mathbf{X}_n(t) : 0 \leq t \leq \Delta t\}_{n=1}^N, \tag{39}$$

where the initial points $\mathbf{X}_n(0)$ are drawn from a *sampling measure* μ, which we will define in the following subsection. To discretize Eq. (33), we first eliminate the numerically problematic limit $\Delta t \to 0$ and integrate the equation using Dynkin's Formula [8, 1]: for any stopping time $\theta > 0$,

$$\mathbb{E}_\mathbf{x}[f(\mathbf{X}(\theta))] = f(\mathbf{x}) + \mathbb{E}_\mathbf{x}\left[\int_0^\theta \mathcal{L}f(\mathbf{X}(t))\,dt\right] \tag{40}$$

Here we take $\theta = \min(\Delta t, \tau)$, where τ is the first-hitting time to the metastable sets $A \cup B$ (viz. Eq. (16)). In other words, we artificially halt the nth trajectory $\mathbf{X}_n(t)$ if it wanders into $A \cup B$ before the terminal time Δt. The nth stopping time from the data set is called θ_n. The operator on the left-hand side of (40) is known as the *stopped* transition operator $\mathcal{T}^\theta$. Applying it to the unknown forecast function F_Γ^+ in (33) and using the fact $\mathcal{L}F_\Gamma^+ = -\lambda\Gamma F_\Gamma^+$, we get

$$\mathcal{T}^\theta F_\Gamma^+(\mathbf{x};\lambda) = F_\Gamma^+(\mathbf{x};\lambda) - \lambda\mathbb{E}_\mathbf{x}\left[\int_0^\theta \Gamma(\mathbf{X}(t))F_\Gamma^+(\mathbf{X}(t);\lambda)\,dt\right] \tag{41}$$

To be more concise, we define the integral operator $\mathcal{I}_\Gamma^\theta f(\mathbf{x}) = \mathbb{E}_\mathbf{x}\left[\int_0^\theta \Gamma(\mathbf{X}(t)) f(\mathbf{X}(t))\, dt\right]$, and write an integrated version of (33):

$$\begin{cases} (\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta) F_\Gamma^+(\mathbf{x};\lambda) = 0 & \mathbf{x} \in D \\ F_\Gamma^+(\mathbf{x};\lambda) = 0 & \mathbf{x} \in A \\ F_\Gamma^+(\mathbf{x};\lambda) = 1 & \mathbf{x} \in B \end{cases} \tag{42}$$

To discretize this equation and impose regularity on the solution, we approximate F_Γ^+ as a finite linear combination:

$$F_\Gamma^+(\mathbf{x};\lambda) \approx \hat{F}_\Gamma^+(\mathbf{x};\lambda) + \sum_{j=1}^M c_j(\lambda)\phi_j(\mathbf{x};\lambda) \tag{43}$$

where $\hat{F}_\Gamma^+$ is a guess function obeying the boundary conditions on $A \cup B$, and $\{\phi_j\}_{j=1}^M$ is a collection of basis functions that are zero on $A \cup B$, which will be defined in the following subsection. The task is now to solve for the coefficients $c_j(\lambda)$. Equation (42) becomes a system of linear equations in $c_j(\lambda)$:

$$\sum_{j=1}^M c_j(\lambda)(\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\phi_j(\mathbf{x};\lambda) = -(\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\hat{F}_\Gamma^+(\mathbf{x};\lambda) \tag{44}$$

Since the transfer and integral operators are expectations over the future state of the system beginning at $\mathbf{x}$, we can estimate their action at $\mathbf{x} = \mathbf{X}_n(0)$ (a short-trajectory starting point) as

$$(\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\phi_j(\mathbf{X}_n(0);\lambda) \approx \phi_j(\mathbf{X}_n(\theta_n);\lambda) - \phi_j(\mathbf{X}_n(0);\lambda) \tag{45}$$
$$+ \lambda \int_0^{\theta_n} \Gamma(\mathbf{X}_n(t))\phi_j(\mathbf{X}_n(t);\lambda)\, dt$$

or, if multiple independent trajectories are launched from $\mathbf{x}$, we can average over them. Applying this to every short trajectory and plugging into Eq. (44), we obtain a system of N equations in M unknowns. In practice, $N \gg M$, meaning we have many more trajectories than basis functions, and the system is overdetermined. A unique solution is obtained by casting it into weak form: we multiply both sides by $\phi_i(\mathbf{x})$ and integrate over state space:

$$\sum_{j=1}^M c_j(\lambda)\left\langle \phi_i, (\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\phi_j \right\rangle_\zeta = -\left\langle \phi_i, (\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\hat{F}_\Gamma^+ \right\rangle_\zeta \tag{46}$$

where the inner products are defined with respect to a measure ζ:

$$\langle f, g \rangle_\zeta = \int f(\mathbf{x}) g(\mathbf{x}) \zeta(\mathbf{x})\, d\mathbf{x} \tag{47}$$

With our finite data set, we approximate the inner product by a sum over pairs of points. Given that $\mathbf{X}_n(0) \sim \mu$, the law of large numbers ensures that for any bounded function $H(\mathbf{x})$,

$$\frac{1}{N}\sum_{n=1}^N H(\mathbf{X}_n(0)) \approx \int H(\mathbf{x})\mu(\mathbf{x})\, d\mathbf{x} \tag{48}$$

becomes more accurate as $N \to \infty$. Thus we set $H(\mathbf{x}) = \phi_i(\mathbf{x})(\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\phi_j(\mathbf{x})$ as estimated by (45), approximate the inner products with $\zeta = \mu$, plug them into (46), and solve the $M \times M$ system of linear equations for $c_j(\lambda)$.

Next we address (37). The integrated version of (37) is found by observing that for any bounded function H,

$$\mathbb{E}_{\mathbf{X}(0) \sim \pi}[H(\mathbf{X}(\Delta t))] = \mathbb{E}_{\mathbf{X}(\Delta t) \sim \pi}[H(\mathbf{X}(\Delta t))] \tag{49}$$

where $\mathbf{X}(0) \sim \pi$ means the initial condition is drawn from equilibrium, and thus so is $\mathbf{X}(\Delta t)$ since π is stationary. Of course, our initial data is *not* distributed according to π, but rather by μ; the goal is to solve for the *change of measure* $w(\mathbf{x}) = \frac{d\pi}{d\mu}(\mathbf{x})$. Writing (49) as an integral,

$$\int \mathcal{T}^{\Delta t} H(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} = \int H(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{50}$$

$$0 = \int (\mathcal{T}^{\Delta t} - 1) H(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{51}$$

$$= \int (\mathcal{T}^{\Delta t} - 1) H(\mathbf{x}) w(\mathbf{x}) \mu(\mathbf{x}) \, d\mathbf{x} \tag{52}$$

$$= \left\langle (\mathcal{T}^{\Delta t} - 1) H, w \right\rangle_\mu \tag{53}$$

As this holds for every bounded H, we enforce the equation for $H = \phi_i$, $i = 1, \dots, M$ and approximate $w = \sum_{j=1}^M c_j \phi_j$, resulting in a homogeneous linear system for the coefficients c_j similar to (46). The matrix elements are

$$\langle (\mathcal{T}^{\Delta t} - 1)\phi_i, \phi_j \rangle_\mu = \langle \phi_i, (\mathcal{T}^{\Delta t} - 1)_\mu^* \phi_j \rangle_\mu \tag{54}$$

where $(\cdot)_\mu^*$ denotes the adjoint operator with respect to μ. Dividing by Δt and taking the limit $\Delta t \to 0$ gives us the strong form of the Fokker-Planck equation, (37). We solve this homogeneous system by QR decomposition. Note that there are no boundary conditions, and the trajectories need not be stopped early. Instead there is a normalization condition, which we enforce as $\sum_{n=1}^N w(\mathbf{X}_n(0)) = 1$. Furthermore, the basis $\{\phi_j\}$ is different between w and F_Γ^+. To ensure that the matrix has a nontrivial null vector, one can add a constant vector to the basis. However, the specific basis we explain below guarantees a null space automatically. Given the weights $w(\mathbf{X}_n(0))$, we can take any ergodic average Γ by inserting the change of measure:

$$\langle \Gamma \rangle_\pi = \int_{\mathbb{R}^d} \Gamma(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} = \int_{\mathbb{R}^d} \Gamma(\mathbf{x}) \approx \sum_{n=1}^N \Gamma(\mathbf{X}_n(0)) w(\mathbf{X}_n(0)) \tag{55}$$

Finally, we address the time-reversed Kolmogorov equation (35). The only modification from (33) is that the inner products in (46) are interpreted in backward time, i.e., with all trajectories reversed, $\mathbf{X}_n(\Delta t)$ becoming the beginning and $\mathbf{X}_n(0)$ becoming the end. The problem is that $\mathbf{X}_n(\Delta t)$ is not distributed according to μ, and so we cannot use the same Monte Carlo inner product as in Eq. (48) with reference measure $\zeta = \pi$. However, we can solve the problem by reweighting with the change of measure as follows, leading to $\zeta = \pi$. We let the trajectory be discrete in time, i.e.,

$$\mathbf{X}_n = \left[\mathbf{X}_n(0), \mathbf{X}_n\left(\frac{\Delta t}{K}\right), \mathbf{X}_n\left(\frac{2\Delta t}{K}\right), \dots, \mathbf{X}_n(\Delta t) \right] \tag{56}$$

and consider functionals $H[\mathbf{X}_n]$ of the whole trajectory. Defining the transition density $p(\mathbf{x},\mathbf{y})$ for each step of size Δt, the expectation of H with $\mathbf{X}_n(0) \sim \pi$ is given by

$$\mathbb{E}_{\mathbf{X}(0)\sim\pi} H[\mathbf{X}] = \int d\mathbf{x}_0 \pi(\mathbf{x}_0) \int d\mathbf{x}_1 p(\mathbf{x}_0,\mathbf{x}_1) \int \dots \int d\mathbf{x}_K p(\mathbf{x}_{K-1},\mathbf{x}_K) H[\mathbf{x}_0,\dots,\mathbf{x}_K] \quad (57)$$

The time reversal step explicitly assumes the *equilibrium* backward process, leading to a backward transition kernel $\widetilde{p}(\mathbf{y},\mathbf{x}) = \frac{\pi(\mathbf{x})}{\pi(\mathbf{y})} p(\mathbf{x},\mathbf{y})$. Inserting this throughout converts the expectation over $\mathbf{X}(0)$ into an expectation over $\mathbf{X}(\Delta t)$:

$$\mathbb{E}_{\mathbf{X}(0)\sim\pi} H[\mathbf{X}] = \int d\mathbf{x}_0 \pi(\mathbf{x}_0) \int d\mathbf{x}_1 \frac{\pi(\mathbf{x}_1)}{\pi(\mathbf{x}_0)} \widetilde{p}(\mathbf{x}_1,\mathbf{x}_0) \int \quad (58)$$

$$\dots \int d\mathbf{x}_K \frac{\pi(\mathbf{x}_K)}{\pi(\mathbf{x}_{K-1})} \widetilde{p}(\mathbf{x}_K,\mathbf{x}_{K-1}) H[\mathbf{x}_0,\dots,\mathbf{x}_K] \quad (59)$$

$$= \int d\mathbf{x}_K \pi(\mathbf{x}_K) \int d\mathbf{x}_{K-1} \widetilde{p}(\mathbf{x}_K,\mathbf{x}_{K-1}) \int \dots \int d\mathbf{x}_0 \widetilde{p}(\mathbf{x}_1,\mathbf{x}_0) H[\mathbf{x}_0,\dots,\mathbf{x}_K] \quad (60)$$

$$= \widetilde{\mathbb{E}}_{\mathbf{X}(\Delta t)\sim\pi} H[\mathbf{X}] \quad (61)$$

where $\widetilde{\mathbb{E}}$ denotes backward-in-time expectation. This is precisely what we need to apply (48) to the time-reversed process, namely

$$\phi_i(\mathbf{X}(\Delta t))(\mathcal{T}^\theta - 1 + \lambda \mathcal{I}_\Gamma^\theta)\phi_j(\mathbf{X}(\Delta t)) = H[\mathbf{X}] \quad (62)$$

$$\langle \phi_i, (\widetilde{\mathcal{T}}^\theta - 1 + \lambda \widetilde{\mathcal{I}}_\Gamma^\theta)\phi_j \rangle_\pi = \widetilde{\mathbb{E}}_{\mathbf{X}(\Delta t)\sim\pi} H[\mathbf{X}] \quad (63)$$

$$= \mathbb{E}_{\mathbf{X}(0)\sim\pi} H[\mathbf{X}] \approx \sum_{n=1}^N H[\mathbf{X}_n] w(\mathbf{X}_n(0)) \quad (64)$$

The right-hand side of Eq. (48) can be estimated similarly, also with $\zeta = \pi$.

In both forward- and backward-time estimates, we never solve for $F_\Gamma^+(\mathbf{x};\lambda)$ or $F_\Gamma^-(\mathbf{x};\lambda)$ with nonzero λ; rather, we repeat the process with Eq. (38).

2.3 Rate estimate

To estimate generalized rates, we reproduce here the rate estimate from [10] for reference, which is an almost-direct implementation of the formula (31), repeated here:

$$R_\Gamma(\lambda) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \times \quad (65)$$
$$\left\{ \mathbb{1}_S \mathcal{T}^{\Delta t}\left[\mathbb{1}_{S^c} F_\Gamma^+\right] - \mathbb{1}_{S^c} \mathcal{T}^{\Delta t}\left[\mathbb{1}_S F_\Gamma^+\right] \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x}$$

While the integral could be estimated directly with any choice of dividing surface S, but the sum would only use data either exiting S (first term) or entering S (second term). We can use all the data at once and improve numerical stability by averaging over multiple such surfaces, and furthermore converting the transition operator $\mathcal{T}^{\Delta t}$ into the generator $\mathcal{L}$. However, we cannot simply take the limit under the integral due to the discontinuity in $\mathbb{1}_S$. Instead we get a smooth function into the

integrand with the following steps. First, replace $\mathbb{1}_S$ with $1 - \mathbb{1}_{S^c}$ everywhere:

$$R_\Gamma(\lambda) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \times \tag{66}$$

$$\left\{ (1 - \mathbb{1}_{S^c}) \mathcal{T}^{\Delta t} \left[\mathbb{1}_{S^c} F_\Gamma^+ \right] - \mathbb{1}_{S^c} \mathcal{T}^{\Delta t} \left[(1 - \mathbb{1}_{S^c}) F_\Gamma^+ \right] \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{67}$$

$$= \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \left\{ \mathcal{T}^{\Delta t} \left[\mathbb{1}_{S^c} F_\Gamma^+ \right] - \mathbb{1}_{S^c} \mathcal{T}^{\Delta t} F_\Gamma^+ \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{68}$$

$$\tag{69}$$

Next, add and subtract $\mathbb{1}_{S^c} F_\Gamma^+$ inside the integrand.

$$R_\Gamma(\lambda) = \lim_{\Delta t \to 0} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \left\{ \frac{\mathcal{T}^{\Delta t} - 1}{\Delta t} \left[\mathbb{1}_{S^c} F_\Gamma^+ \right] - \mathbb{1}_{S^c} \frac{\mathcal{T}^{\Delta t} - 1}{\Delta t} F_\Gamma^+ \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{70}$$

At this point it is tempting to take the limit inside the integral, as $(\mathcal{T}^{\Delta t} - 1)/\Delta t$ formally approaches $\mathcal{L}$. But the first term acts on a discontinuous function, which won't have a well-defined time derivative. We first replace $\mathbb{1}_{S^c}$ with a smooth function (on D), as follows.

Let $K : \mathbb{R}^d \to [0,1]$ be a function that increases from 0 on set A to 1 on set B (for instance, the committor). Let $S_\zeta = \{ \mathbf{x} : K(\mathbf{x}) \leq \zeta \}$ for $\zeta \in (0,1)$, and integrate both sides over ζ, noting that $\int_0^1 \mathbb{1}_{S_\zeta^c}(\mathbf{x}) \, d\zeta = \int_0^1 \mathbb{1}\{K(\mathbf{x}) > \zeta\} \, d\zeta = K(\mathbf{x})$.

$$\int_0^1 R_\Gamma(\lambda) \, d\zeta = \lim_{\Delta t \to 0} \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \left\{ \frac{\mathcal{T}^{\Delta t} - 1}{\Delta t} \left[K F_\Gamma^+ \right] - K \mathcal{L} F_\Gamma^+ \right\}(\mathbf{x}) \pi(\mathbf{x}) \, d\mathbf{x} \tag{71}$$

Now we can move the limit inside and use the PDE to find

$$R_\Gamma(\lambda) = \int_{\mathbb{R}^d} F_\Gamma^-(\mathbf{x};\lambda) \left\{ \mathcal{L}[K F_\Gamma^+](\mathbf{x}) + \lambda K(\mathbf{x}) \Gamma(\mathbf{x}) F_\Gamma^+(\mathbf{x}) \right\} \pi(\mathbf{x}) \, d\mathbf{x} \tag{72}$$

This formula can be estimated directly from knowledge of F_Γ^-, F_Γ^+, and π, using the ergodic assumption and with a discrete finite difference in time to estimate $\mathcal{L}[K F_\Gamma^+]$, i.e.,

$$\mathcal{L}[K F_\Gamma^+](\mathbf{X}_n(0)) \approx \frac{K(\mathbf{X}_n(\Delta t)) F_\Gamma^+(\mathbf{X}_n(\Delta t)) - K(\mathbf{X}_n(0)) F_\Gamma^+(\mathbf{X}_n(0))}{\Delta t} \tag{73}$$

Derivatives with respect to λ can be found by iterating the product rule, as we have solved for the derivatives of F_Γ^+ and F_Γ^-.

2.4   Reactive current projection and flux distributions

The formulas above follow closely those in [10], but generalize slightly by using forecasts F_Γ^+ and F_Γ^- rather than just q^+ and q^-. We use the exact same reactive current formula as in the supplement of [10], but repeat it here for reference. We have defined the current informally in d-dimensional space, but in Figure 5 we have projected it onto a two-dimensional observable subspace. Let $\mathbf{y} = \mathbf{Y}(\mathbf{x})$ be an observable subspace, typically with dimension much less than that of $\mathbf{x}$. The *projected current* is defined as

$$\mathbf{J}_{AB}^{\mathbf{Y}}(\mathbf{y}) = \int \mathbf{J}_{AB}(\mathbf{x}) \cdot \nabla \mathbf{Y}(\mathbf{x}) \pi(\mathbf{x}) \delta(\mathbf{Y}(\mathbf{x}) - \mathbf{y}) \, d\mathbf{x} \tag{74}$$

12

In practice, the **y** space is partitioned into grid boxes $d\mathbf{y}$, in which the discretized projected current is

$$\mathbf{J}_{AB}^{\mathbf{Y}}(\mathbf{y}) \approx \frac{1}{2\Delta t} \sum_{n=1}^{N} w(\mathbf{X}_n(0)) \left[\mathbb{1}_{d\mathbf{y}}(\mathbf{X}_n(0)) q^-(\mathbf{X}_n(0)) q^+(\mathbf{X}_n(\theta_n)) \frac{\mathbf{Y}(\mathbf{X}_n(\theta_n)) - \mathbf{Y}(\mathbf{X}_n(0))}{\theta_n} \right. \tag{75}$$

$$\left. + \mathbb{1}_{d\mathbf{y}}(\mathbf{X}_n(\Delta t)) q^-(\mathbf{X}_n(\widetilde{\theta}_n)) q^+(\mathbf{X}_n(\Delta t)) \frac{\mathbf{Y}(\mathbf{X}_n(\Delta t)) - \mathbf{Y}(\mathbf{X}_n(\widetilde{\theta}_n))}{\Delta t - \widetilde{\theta}_n} \right] \tag{76}$$

where θ_n and $\widetilde{\theta}_n$ are the "first-entry times" to $D = (A \cup B)^{\mathrm{c}}$ in the nth trajectory with time running forward and backward, respectively.

We make use of the same formula to compute the flux distribution across a surface of constant lead time ($\mathbf{Y} = \eta^+$) or committor ($\mathbf{Y} = q^+$). The first and second terms in brackets represent contributions from the forward and backward generators, respectively. The flux contribution from the nth trajectory segment, therefore, is the average of those two terms. In selecting a set of candidate trajectories for a given level set, say of q^+, we choose trajectories whose *midpoint* has a q^+ value close to that level, and among those candidates only those whose contribution is greater than 10% of the maximum. This defines the discrete sampling of the distribution from which we extract weighted averages and quantiles for the max-flux path in Fig. 7.

2.5 Algorithmic parameters

Having sketched the general numerical procedure, we now provide the exact parameters used here, which are similar to those in [3]. We use $N = 3 \times 10^5$ trajectories, each of length $\Delta t = 20$ days, with a sampling interval of 1 day. The initial conditions are resampled from a long (2×10^5-day) control simulation to be uniformly distributed on the space $(|\Psi|(30\,\mathrm{km}), U(30\,\mathrm{km}))$. With a more complex, expensive model, we cannot rely on a control simulation to seed the initial points, but here we focus on TPT and DGA as a proof of concept rather than optimizing the numerical procedure. We use $M = 1200$ basis functions defined as indicators on a partition induced by K-means clustering on $\{\mathbf{X}_n(0)\}$. The clustering is hierarchical so that the cluster size does not become too imbalanced.

There are many potential directions for methodological improvement. In an expensive model without the ability to run a long control simulation, we should use a splitting and killing method to seed the initial trajectories across state space. Moreover, we could perform DGA repeatedly with new data seeded at each iteration in areas of high sensitivity. The choice of basis function can also powerfully affect DGA's performance. Indicator functions are advantageous in producing a bona fide Markov matrix and guaranteeing a maximum principle for the committor probabilities. However, smooth and/or global basis functions have in some cases found to be more efficient at capturing the structure of the committor with fewer basis elements [11, 10]. It would also behoove future experiments to repeat the procedure with multiple random seeds for the short trajectories, and thereby estimate a DGA variance that can be assessed alongside DNS variance.

3 Minimum-action method

To compute the minimum-action paths, we use a completely discrete approach for simplicity and to accommodate the low-rank nature of the stochastic forcing. Heuristically, we wish to find the most probable path connecting A and B, which we take as the mode of the (discretized) path density over the distribution of paths from A to B. For concreteness, fix $\mathbf{x}(0) = \mathbf{x}_0 \in A$ and a time horizon T discretized into K intervals, with a timestep $\delta t = T/K = 0.005$ days. The discretized dynamics evolve

according to the Euler-Maruyama method as

$$\mathbf{x}(k\delta t) = \mathbf{x}((k-1)\delta t) + \nu\big(\mathbf{x}((k-1)\Delta t)\big)\Delta t + \sigma\boldsymbol{\eta}_k\sqrt{\delta t} \tag{77}$$

where $\boldsymbol{\eta}_k$ is a vector of i.i.d. unit normal samples, ν is the deterministic drift, and $\sigma \in \mathbb{R}^{d \times m}$ is the diffusion matrix, with a noise rank $m = 3$ and a spatially smooth structure as defined in [3]. In the classical minimum-action approach, σ is assumed to be a $d \times d$ invertible matrix, and the probability density of a path $(\mathbf{x}_0, \dots, \mathbf{x}_K)$ (where $\mathbf{x}_k = \mathbf{x}(k\delta t)$) is

$$\prod_{k=1}^{K} \mathcal{N}\Big(\mathbf{x}_k \Big| \mathbf{x}_{k-1} + \nu(\mathbf{x}_{k-1})\delta t, \sigma\sigma^\top \delta t\Big) \tag{78}$$

$$= \prod_{k=1}^{K} \frac{1}{(2\pi\delta t)^{dK/2}(\det\sigma)^K} \times \tag{79}$$

$$\exp\left\{ -\frac{1}{2}\Big(\mathbf{x}_k - \mathbf{x}_{k-1} - \nu(\mathbf{x}_{k-1})\delta t\Big)^\top \frac{(\sigma\sigma^\top)^{-1}}{\delta t} \Big(\mathbf{x}_k - \mathbf{x}_{k-1} - \nu(\mathbf{x}_{k-1})\delta t\Big) \right\} \tag{80}$$

$$\propto \exp\left\{ -\frac{\delta t}{2} \sum_{k=1}^{K} \left(\frac{\mathbf{x}_k - \mathbf{x}_{k-1}}{\delta t} - \nu(\mathbf{x}_{k-1})\right)^\top (\sigma\sigma^\top)^{-1} \left(\frac{\mathbf{x}_k - \mathbf{x}_{k-1}}{\delta t} - \nu(\mathbf{x}_{k-1})\right) \right\} \tag{81}$$

$$\sim \exp\left\{ -\frac{1}{2} \int_0^T \Big[\dot{\mathbf{x}}(t) - \nu(\mathbf{x}(t))\Big](\sigma\sigma^\top)^{-1}\Big[\dot{\mathbf{x}}(t) - \nu(\mathbf{x}(t))\Big] dt \right\} \text{ as } \delta t \to 0 \tag{82}$$

and the problem becomes to minimize the quadratic form in the argument of the exponential, which is the Freidlin-Wentzell action functional, subject to the constraint $\mathbf{x}_K \in B$. However, because we stir the wind field with smooth spatial forcing in only $m \ll d$ wavenumbers, σ is low-rank and thus $\sigma\sigma^\top$ is singular. Given any realized path $(\mathbf{x}_0, \dots, \mathbf{x}_K)$, there may be no possible underlying forcing $\boldsymbol{\eta}_k$ that could have produced it under our noise model. So the obvious optimization strategy of fixing $\mathbf{x}_0$ and $\mathbf{x}_K$ and varying the steps in between may lead to impossible paths. For this reason, we perform optimization in the space of perturbations, and ensure that every step of the optimization is realizable under our noise model. This is a strategy we adopt from the cyclogenesis model [9]. The result will be a simpler, convex objective function at the expense of a more complicated constraint. The probability density of a particular forcing sequence $(\boldsymbol{\eta}_1, \dots, \boldsymbol{\eta}_K)$ is given by

$$\prod_{k=1}^{K} \frac{1}{(2\pi)^{m/2}} \exp\left(-\frac{1}{2}\boldsymbol{\eta}_k^\top \boldsymbol{\eta}_k\right) = \frac{1}{(2\pi)^{mK/2}} \exp\left(-\frac{1}{2}\sum_{k=1}^{K}\boldsymbol{\eta}_k^\top \boldsymbol{\eta}_k\right) \tag{83}$$

The objective inside the exponential is now a simple quadratic in perturbation space which can be easily differentiated with respect to those perturbations. The constraint, meanwhile, takes the form of a complicated iterated function. Define the flow map $F(\mathbf{x}) = \mathbf{x} + \nu(\mathbf{x})\delta t$ as the deterministic part of the timestep, so $\mathbf{x}_k = F(\mathbf{x}_{k-1}) + \sigma\boldsymbol{\eta}_k\sqrt{\delta t}$. In terms of F, the endpoint has to be written as a recursive function

$$\mathbf{x}_K = F(\mathbf{x}_{K-1}) + \sigma\boldsymbol{\eta}_K\sqrt{\delta t} \tag{84}$$

$$\mathbf{x}_{K-1} = F(\mathbf{x}_{K-2}) + \sigma\boldsymbol{\eta}_{K-1}\sqrt{\delta t} \tag{85}$$

$$\vdots \tag{86}$$

$$\mathbf{x}_1 = F(\mathbf{x}_0) + \sigma\boldsymbol{\eta}_1\sqrt{\delta t} \tag{87}$$

14

We impose the end constraint by adding to the action a penalty $\Phi(\mathbf{x}_K) = \text{dist}(\mathbf{x}_K, B)$, a function which linearly increases with distance to B. The full optimization problem is

$$\min_{\boldsymbol{\eta}} \left\{ \frac{1}{2K} \sum_{k=1}^{K} \boldsymbol{\eta}_k^\top \boldsymbol{\eta}_k + \alpha \Phi(\mathbf{x}_K) \right\} \tag{88}$$

$$\mathbf{x}_0 \in A \text{ is fixed} \tag{89}$$

$$\mathbf{x}_k = F(\mathbf{x}_{k-1}) + \sigma \boldsymbol{\eta}_k \sqrt{\delta t} \text{ for } k = 1, \dots, K \tag{90}$$

Here α is a weight which can be increased to harden the end constraint. We divide by K so that the path action does not overwhelm the endpoint penalty as $K \to \infty$. (This makes the sum converge to an integral.) We set $\mathbf{x}_0$ to be the fixed point $\mathbf{a} \in A$ when finding the least-action path from A to B and the fixed point $\mathbf{b} \in B$ when finding the least-action path from B to A. We used the L-BFGS method as implemented in `scipy`, with a maximum of 10 iterations. We differentiate $\Phi(x_K)$ with respect to $\boldsymbol{\eta}_k$ using knowledge of the adjoint model, with a backward pass through the path to compute each gradient. At each descent step, we refine the stepsize with backtracking line search. One way to guarantee the end constraint is ultimately satisfied is to gradually increase α and lengthen T; however, we found it sufficient to fix $\alpha = 1.0$ and $T = 100$, in keeping with the typical observed transit time. We have kept the algorithm simple, not devoting too much effort to finding the global optimimum over all time horizons, as we only care for a qualitative assessment to compare with results of TPT.
